Chapter 2

Background

2.1 Village Telco

2.2 Mesh Potato

The whole concept around the Mesh Potato was developed in June 2008 during a workshop at the Shuttleworth Foundation. The main goal was to figure out how to develop an inexpensive system to provide rural and under-served areas with affordable telephone communication [?]. Including participants like open hardware pioneer Dawid Rowe and Elektra, the developer of the B.A.T.M.A.N. mesh networking protocol [3]. The aim of the workshop was to develop a business model as well as a prototype for a Village Telco. Initially the idea was to use low cost VoIP headsets. At that time it was the most viable and convenient way to deliver telephone services to the customers. With a VoIP telephone services the nodes can not be more than 100 meters away from each other, requiring more nodes in order to cover the desirable area. Which again would drastically increase the start-up costs for a village. In order to keep the cost down, it was also important to keep the number of access points down. A mesh network have a larger range, and one suggestion was to use a small mesh device like a Open Mesh AP and connect a SIP phone to it. This solution would solve a lot of the problems regarding range, antenna and number of access points, but the idea was still an expensive option. The challenge was to create something that would be simple enough to be implemented and scaled by local entrepreneurs with limited technical skills. As well as keeping the cost down. The two key cost factors that emerged in the scale-up of a Village Telco were the cost of the customer's phone and the power supply. It was clear that the the power supply was the most important factor and the work started in driving the cost of the phone down [3]. During the debating, Rael Lissoos took a Analogue Telephone Adapter (ATA) and an Open Mesh AP, held them together and said that we need these two devices in one. These small OpenMesh devices are able to run an adapted version of the B.A.T.M.A.N. protocol, called Robin. This point was the birth of the

4 2. BACKGROUND

Mesh Potato, fully based on customized open hardware and open software design. The name comes from combining the words mesh, POTS (Plain Old Telephone) and ATA. "Patata" is the Spanish word for potato, and hence the name Mesh Potato. A mesh enabled WiFi device with the possibility to connect any inexpensive regular phone and IP device. [4]

Figure 2.1: The fist generation Mesh Potato, MP01

The First generation of the Mesh Potato is shown in Figure 2.1. This device is designed to be used in rural areas. It can be deployed and run anywhere in the world relying only on a low, but stable, power supply. The Ethernet port, Foreign eXchange Station (FXS) ports and power are robust and designed in order to handle hard weather, poor power conditions, lightening and static electricity. In addition the Mesh Potato comes in a waterproof box for outdoor mounting [5].

The Mesh Potato combines the features of a 802.11bg WiFi router with an Analog telephone Adaptor (ATA) [6]. The ATA converts the signal from a standard telephone into the digital signal needed to connect to the internet and use the SIP protocol [?]. Each Mesh Potato provides a single fixed telephone line to the end user. The MPs are connected together via a mesh WiFi network, and configure themselves automatically to form a peer-to-peer network, greatly extending the range of the network over regular WiFi. Enabling phone calls to be made independent of landlines and telephone towers. Creating the basis for the "plug-and-play" solution.

As mentioned the Mesh Potato is open, based on open hardware as well as open software design. Everything is kept open in order for any thisrd party to come with feedback, test an set standards. Some of the key goals while developing was to minimize the binarly bolbs, propriertily software and make the hardware open.

The device is based on the Atheros chipset that if used, among others, by OpenMesh, and would run OpenWRT and B.A.T.M.A.N.

The Mesh network can be connected via a backbone link to the rest of the world by using VoIP gateways. No cell phone towers, no land lines, and no big telcos required. A Village Telco is a community owned telephony, allowing a local entrepreneur to roll out the Village Telco system only needing a server and the wanted amount of Mesh Potatoes. The mesh network is self healing and self organizing, meaning if one node goes down, B.A.T.M.A.N. routes the calls through other available nodes in the network [7]. In order to provide internet access a super node have to be placed in connection with an internet connection. The internet signal enters the server in the Village Telco, this could for example be an existing internet café, vis a broadband, link or satellite. The signal is transmitted by the super node. the super node consists of three external access points, and is placed high over ground, giving a 360 degree coverage, with approximately 1 km range. The Internet signal is then carried through the network from one MP to another.

Difference between MP01 and MP02?

2.3 Technology

2.3.1 Ad Hoc and Mesh Networks

Figure 2.2: Cellular network vs. MANET. This figure illustrates the difference between a regular cellular network and a mobile ad hoc network [8].

MANETs

Mobile ad hoc networks (MANETs) are networks that does not rely on an underlying and fixed infrastructure (access points and routers), in other words infrastructureless. MANETs acts in a shared wireless media [1]. The structure of these networks change

dynamically, and key factors for MANETs is self-configuration and self-organization. The members of the network are mobile and are free to join or leave the network [8], and therefore these factors are important. MANETs are based on multi-hop forwarding. This means that each node acts not only as a host, but also as a router. The nodes themselves establishes and maintain routes, and forward packets to other nodes if necessary. This enables communication between nodes that are originally not within each other's send range [8]. Because of these characteristics MANETs is suited for use in situations where there are no fixed underlying infrastructure. MANETs can operate as a stand-alone solution, but it can also be attached to the Internet. This makes room for numerous of services.

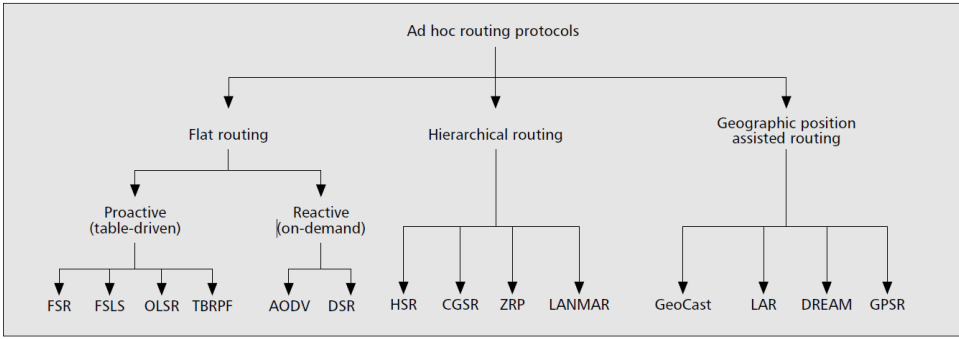

Figure 2.3: Different groups of ad hoc routing protocols [1].

Routing Protocols

There exists many challenges when it comes to these types of networks. The routing protocols must be able to adapt quickly due to the topology changes. Figure 2.3 shows the different groups of the ad hoc protocols that exist. The routing protocols must not cause excessive overhead. Under the category flat routing, there are two types of routing protocols; proactive and reactive. *Proactive routing protocols* (e.g. OLSR) are table driven [9]. This means that every network node has a routing table for the forwarding of data. To obtain stability, each node broadcasts and modifies the routing table periodically. Proactive routing protocols are suitable when there are few nodes in the network. Because of the routing table that is periodically updated, the overhead exceeds the desired value when there are a high number of nodes in the network. In contrary to the proactive routing protocols, *reactive routing protocols* (e.g. AODV) are on demand. Since they are on demand, the overhead is significantly lower. These protocols utilizes flooding. The network is flooded with the route request (RREQ) in order to set up the route. The reactive routing protocols does not have a up-to-date routing table like proactive routing protocols [9]. Routes are only

set up to nodes they communicate with, and these routes are only kept alive while they are needed [8]. As shown in Figure 2.3, there are several different protocols under proactive and reactive.

B.A.T.M.A.N Better Approach To Mobile Adhoc Networking (B.A.T.M.A.N) is the routing protocol utilized in the networks formed by the Mesh Potatoes. B.A.T.M.A.N is a proactive routing protocol for wireless ad hoc networks. This includes MANETs [10]. This protocol was developed as an alternative to OLSR (Optimized Link State Routing) [2]. Like mentioned before, routing protocols must be able to adapt quickly to topology changes. B.A.T.M.A.N was made to be a more efficient routing protocol in this area, since it employs a new method for discovering routes. The nodes in the network broadcasts a OGM periodically. A OGM is a Originator Message which contains:

- The address of the node
- Sequence number
- TTL (Time to live)

The address and the sequence number enables identification of a packet and duplicate detection.

Figure 2.4: SKRIVE NOE HER [2].

Information about the nodes that are accessible via single-hop or multi-hop are maintained and updated [10]. Every node updates its routing table each time it receives an OGM. The routing table includes information about [2]:

Originator Address

This is the source address of the node that sent the OGM.

Current Sequence Number

The sequence number of the last OGM. This is used to discover if there are any duplicates or any information that is outdated.

Sliding Window

A list of sequence numbers that is stored for each originator and each previous hop, i.e., for the neighbour node that forwarded or originated the OGM.

When a node receives an OGM it will decrease the TTL, and then forward it to the neighbour nodes. The same OGM can arrive to a node, but from a different paths. In this case, only the first copy is preserved.
